(Received: 10 January 2007; accepted: 18 February 2007)

The study deals with comparative analysis of xanthan gum production, pyruvate, acetate and protein content of *Xanthomonas campestris* MTCC 2286 and *Xanthomonas malvacerum*. The *Xanthomonas malvacerum* isolated strain could be useful in oil recovery process. *Xanthomonas malvacerum* has produced high level of xanthan gum (16.8g/l). It is observed from the results that addition of citric acid in the fermentation medium, increases xanthan gum concentration.

**Keywords:** *Xanthomonas campestris*, *Xanthomonas malvacerum* and xanthan gum

---

The isolation and screening of *Xanthomonas* strains from natural habitats is an important tool to improve xanthan gum production. Industrially produced microbial polysaccharides xanthan gum is the most important. It is produced by *Xanthomonas campestris* (Galindo, 1994a) and has applications in many industrial fields such as textiles, ceramics, agricultural production, food production, oil recovery (Kennedy & Bradshaw 1984). *Xanthomonas campestris* is phytopathogenic bacteria which cause black rot in crucifers (Sutton & Williams 1970).

Xanthan gum production has been performed with strains from culture collections, especially *Xanthomonas campestris* NRRL B-1459. There has been relatively little work on production by wild strains (Torrestiana *et al.*, 1990). Ramirex *et al.*, 1988 suggested virulence in plants was a good indicator of gum production. There are very few reports dealing with the characterization reported the isolation of 21 strains of *Xanthomonas campestris* from tropical regions and the viscosity of the fermentation broth was measured in a Brookfield viscometer. Comparison of wild type *Xanthomonas* strains with *Xanthomonas malvacerum* isolates has not been previously reported. The aim of the present work is selection, characterization and production of xanthan gum from *Xanthomonas malvacerum* strain isolated form infected cotton leaves with *Xanthomonas campestris* MTCC 2286.

**MATERIALS AND METHODS**

**Isolation of strain**

*Xanthomonas malvacerum* was isolated from infected cotton leaves. This isolate was assessed by a shake flask for xanthan productivity test (Galindo *et al.*, 1993). A variant of the collected strain *Xanthomonas campestris* MTCC 2286 was used for comparative studies.

**Fermentation Media**

YM medium was used for inoculum development of *Xanthomonas campestris* (Flores *et al.*, 1994).
The composition of the production medium was
(g/l): glucose 24; peptone 0.8; KH$_2$PO$_4$ 3.068;
(NH$_4$)$_2$PO$_4$ 0.6973; citric acid 1.3; Mg SO$_4$ 0.23;
FeCl$_3$ 0.0014; CaCO$_3$ 0.0024; H$_3$BO$_3$ 0.0048; ZnO,
0.0072; pH was adjusted to 7.2.

Isolation of Xanthomonas malvacerum from infected leaves
The blight infected leaves were collected from the
cotton field. The diseased spots were dissected out,
the surface was sterilized with mercuric chloride
(0.1% W/V), than thoroughly washed with sterile
distilled water and transferred aseptically to
Hoitink and Sindern’s (HS) medium plates.
The plates were incubated at 29° C for three days.
A yellow bacterium was grown from the leaf spots
and it was confirmed by the routine bacteriological
test (Bergey’s manual of systematic bacteriology
1984).

Fermentation process
Wild and isolated strain were cultured in duplicate
in 500ml production medium in 2000ml flasks
for 48hrs at 29° C in an incubator shaker at 200rpm.
The inocula 10% V/V was used for xanthan production.

Analytical procedures
Bacterial cell mass was determined by dry weight
method at various time intervals. Xanthan gum
was recovered by precipitation with two volumes
of isopropyl alcohol using 2% W/W potassium
chloride as electrolyte. The product was dried in
an oven at 40° C for 24hrs.
The content of polysaccharide per gram
of product was determined according to the
sulphuric acid – resorcinol method (Graham
1971). Estimation of glucose concentration was
determined by DNS method. Pyruvic acid was
estimated by the enzymatic method of
Hadjivassiloic and Rieder (1968). Acetyl residues
were determined by the colorimetric method
reported by Mc Comb and Mc Cready (1957).
Nitrogen was determined by the Lowry method.

RESULTS AND DISCUSSION
The time course of xanthan biosynthesis, cell
concentration and glucose consumption was
shown in Table 1. The yield of xanthan productivity
from 0.04 to 0.05 (g xanthan per g of glucose
consumed) in Xanthomonas malvacerum. But the
production of xanthan in Xanthomonas campestris
was 0.21 to 0.37 g of xanthan /gm of glucose.
A corresponding increase in specific xanthan
production from 1.25 to 1.42g of xanthan /g of
cell and from 1.1 to 1.54 gm of xanthan /gm in
Xanthomonas malvacerum and Xanthomonas
campestris respectively. Jana and Ghosh (1997)
reported that due to better oxygen transfer and
mixing behaviour in the fermentation broth the
yield of xanthan (g xanthan per gm of glucose
consumed) also increased from 0.49 to 0.59.
The effect of citric acid on xanthan
production was observed in Table 2. Different
concentration of citric acid was added after 24hrs
of fermentation in 8hrs interval (ranges from

0.50g/l to 3.0g/l). Citric acid concentration above 3g/l did not improve xanthan production. Citric acid was totally consumed in 24hrs in all case except when the initial concentration of citric acid was 6 or 8g/l. Citric acid above 8g/l however, prevented both cell growth and xanthan synthesis. Increase in xanthan concentration was observed to be dependent on the amount of citric acid added (Table 2). Our results were correlated with the finding of Jana and Ghosh (1997) increased in xanthan concentration from 10.4g/l to 18.6g/l. The chemical composition of the polymers obtained from the Xanthomonas campestris with Xanthomonas malvacerum isolates are compared in Table 3. The xanthan showed a range in acetyl and pyruvic contents, with values similar to those reported from other isolates (Sanchez et al., 1997).

Low pyruvate content was determined in the product from Xanthomonas malvacerum. These could be especially in xanthan applications related to oil recovery processes. Kleinitz et al., (1989) reported that in oil recovery process xanthan with low pyruvate content showed lower adsorption over the soil. Total nitrogen value was determined in the products from Xanthomonas malvacerum and Xanthomonas campestris (1.2% and 1.5%). Sanchez et al., (1997) reported that the range of nitrogen content in the xanthan from four isolates (1.01% to 3.04%). High proteinaceous nitrogen contents could restrict the use of xanthan in application such as food additives or cosmetics.

Characterization showed that the two selected isolates of Xanthomonas campestris and Xanthomonas malvacerum have high potential for xanthan production. Isolate Xanthomonas malvacerum could be useful for the oil recovery process because they exhibited low pyruvate content. In the screening of Xanthomonas malvacerum isolate, the productivity test was compared with Xanthomonas campestris MTCC 2286, and to decide Xanthomonas malvacerum has potential for xanthan production.
